INTRODUCTION

The analysis of the long-term-decay behavior in real relaxation processes is a subject of interest beyond the academic domain. They are important in science, technology and engineering. From a general point of view, the relaxation phenomena observed in physics, biophysics, chemistry, materials science, polymer science, electronics, etc., present many similar characteristics. Nevertheless, their analysis is sometimes ambiguous due to the noise, the uncertainty in the asymptotic limit and the relatively short interval of time during which relaxation data are recorded. This, together with the possibility of fitting the experimental results to different models with equivalent precision makes difficult the identification of the processes involved, although alternatives are sometimes proposed to solve these problems. Moreover, in usual relaxation processes the coexistence of several diverse mechanisms takes place, and their identification during the fitting stage would be desirable, in order to separate them from the others. Then, to avoid these problems, it would be interesting to obtain models based on general considerations that contained a reduced number of parameters to fit.

In this context, the magnetic properties of assemblies of magnetic interacting particles have been studied by Monte Carlo simulations, and recently Ulrich et al. have found that the relaxation rate of the thermoremanent magnetic moment of such assemblies follows a universal power law. Depending on the value of the exponent, it is found stretched exponential decay for diluted magnetic particles and algebraic decay for concentrated ones. These theoretical predictions have been recently confirmed by measurements of relaxation in granular magnetic films.

The evolution towards an equilibrium state in relaxation phenomena is expected to approach a certain stationary regime. Generally the word stationary indicates a process described by time-independent parameters. Here we will use such a basis to try to obtain the functional form of the time decay of the relaxation process of a system when approaching the stationary limit.

THE MODEL

Let a relaxing system be described by a field \( \mathbf{X} \). Its free relaxation is of first-order when the time derivative of first order of \( \mathbf{X} \) is only a function of the non-time-dependence of \( \mathbf{X} \).

\[
\Theta \mathbf{X} - \frac{\partial \mathbf{X}}{\partial t} = 0,
\]

where \( \Theta \) is any spatial-like operator.

A reasonable assumption is that, at long times, the free evolution of the system becomes independent of the initial conditions, and tends to a stationary process. A simple analogy would be a finite relaxing RC network: it tends to a regime where all the capacitors end by discharging with the same time constant. Then, a scalar magnitude \( \psi \), representing any kind of average calculated over the state of the system, can be used to describe it. Let us assume that \( \psi \) is monotonously decreasing (positive) and that \( \lim_{t\to\infty}\psi(t)=0 \). In this stationary limit, \( \psi \) describes the state of the system and therefore its evolution is described by \( \psi(t) \) and its time derivative, \( \psi'(t) \). We want to abstract this stationary concept, with no reference to any particular process. Then, this first-order process should be described by (i) adimensional magnitudes, and (ii) \( \psi \) and its time derivative, without explicit presence of time.

If we now consider two times, \( t_1 \) and \( t_2 \),

\[
\psi_1 = \psi(t_1), \quad \psi_2 = \psi(t_2),
\]

\[
\psi'_1 = \psi'(t_1), \quad \psi'_2 = \psi'(t_2),
\]

the magnitudes

\[
\frac{\psi_1}{\psi_2}, \quad \frac{\psi'_1}{\psi'_2}
\]

fulfill the previous conditions. Any other adimensional magnitude referring to \( t_1 \) and \( t_2 \) would be a function of them. We exclude \( t_1/t_2 \) because it refers explicitly to time and depends on the time origin.

We arrive then at the fact that a first-order process \( \psi(t) \) is stationary if there exists a function \( f \) fulfilling
In order to solve Eq. (2), let us consider two times \( t_1(x) \) and \( t_2(x) \), depending arbitrarily on a parameter \( x \). Deriving with respect to \( x \),

\[
\frac{d}{dx} \phi_1 \left( \frac{\phi'_1}{\phi_2} \right) = \frac{d}{dx} \left( \frac{\phi_2 \phi'_1 dt_1}{dx} - \phi_1 \phi'_2 dt_2 \right).
\]

(3)

Obviously,

\[
\frac{d}{dx} \phi_1 = 0 \Rightarrow \frac{d}{dx} \phi'_1 = 0,
\]

that is,

\[
\phi_2 \phi'_1 dt_1 = \phi_1 \phi'_2 dt_2 \Rightarrow \phi'_1 = \phi'_2 = \phi'_2 dt_2.
\]

(4)

If we choose functions \( t_1(x) \) and \( t_2(x) \) such that the first equality of Eq. (4) is fulfilled, the second will also be fulfilled. In that case, dividing both members of the equations

\[
\frac{\phi_1 \phi''}{\phi_2} = \frac{\phi_2 \phi''}{\phi'_2}.
\]

(5)

We can also choose \( t_1 \) and \( t_2 \) independently, therefore each of the members of Eq. (5) must be constant \( \lambda \),

\[
\frac{\phi \phi''}{\phi'_2} = \lambda.
\]

(6)

In order to solve it, we rewrite it

\[
\pm \phi'' = \lambda \phi
\]

and integrating

\[
\ln |\phi'| = \ln A + \lambda \ln |\phi|
\]

(8)

with \( A \) a positive constant. Then

\[
\phi' = \pm A \phi^\lambda.
\]

(9)

In a monotonous decreasing process we must use the negative sign, and this leads to the following solution:

\[
\psi = \psi_0 e^{-\lambda t}, \quad \lambda = 1,
\]

(10)

\[
\psi = \left( (\lambda - 1)A(t + t_0) \right)^{-1/(\lambda - 1)}, \quad \lambda > 1.
\]

Introducing appropriate constants \( \psi_0, \gamma, \) and \( \tau \), the second solution can be written as

\[
\psi = \psi_0 \left( 1 + \frac{t}{\gamma \tau} \right)^{-\gamma}
\]

(11)

with

\[
\gamma = \frac{1}{\lambda - 1}, \quad 0 \leq \gamma \leq \infty.
\]

(12)

Note that the Debye process \( (\lambda = 1) \) is the simplest case of Eq. (2) \([|\phi'_1/\phi'_2| = 1/\phi_2] \) and, for finite \( t \), is the limit \( \gamma \rightarrow \infty \) of Eq. (11),

\[
\phi_D = \psi_0 e^{-\lambda \tau}.
\]

(13)

Also, it is worth mentioning that, from Eq. (5),

\[
\frac{\phi''}{\phi_2} = g \left( \frac{\phi'_1}{\phi_2} \right)^2.
\]

(14)

Given that the inverse of \( f \) exists \( (\psi \) and \( \psi' \) are strictly monotonous decreasing), the second member is a function of \( \psi'_1/\psi'_2 \),

\[
\frac{\phi''}{\phi_2} = g \left( \frac{\phi'_1}{\phi_2} \right)^2,
\]

which can be extended by induction to higher-order derivatives (i.e., the processes described by the derivatives are also stationary).

**PROPOSAL OF GRAPHICAL REPRESENTATION**

An interesting fact is that these considerations can be used to obtain a useful representation of the relaxation process, in which neither \( \tau \) nor \( t \) appear. Deriving Eq. (10) with respect to \( \ln t \), and expressing the result as a function of \( \psi \), we arrive at

\[
\frac{d\psi}{d \ln t} = - \gamma \psi \left[ 1 - \left( \frac{\psi}{\psi_0} \right)^{1/\gamma} \right].
\]

(16)

If \( d\psi/d \ln t \) versus \( \psi \) is plotted [with \( \psi(0) = \psi_0 = 1 \) and \( \lim_{t \rightarrow \infty} \psi(t) = \psi_{\infty} = 0 \)], the whole relaxation process can be viewed in a finite window (Fig. 1), as in the Cole-Cole representation in the frequency domain, for example.

As a relevant case, it is worth mentioning that the stretched exponential, frequently used in the analysis of relaxation phenomena

\[
\psi_K = \psi_0 e^{-(t/\tau)^\beta},
\]

(17)

appears as

\[
\frac{d\psi_K}{d \ln t} = \beta \psi \ln \frac{\psi}{\psi_0}.
\]

(18)

In this proposed representation, processes \( \psi \) described by Eq. (11) with \( \gamma \rightarrow \infty \) and \( \psi_K \) with \( \beta \rightarrow 1 \) reduce to the Debye process. In cases different enough from this, useful information can be read from the graphs (Fig. 1, with \( \psi_0 = 1 \) and \( \psi_{\infty} = 0 \)).

(i) Near origin, power-law processes have finite slope \( -\gamma \), and stretched exponential ones have it infinite at origin.

(ii) Stretched exponential processes have a minimum at \( 1/e \), whereas power-law processes have minima at points \( \psi_{\min} \) that depend on \( \gamma \).
RESULTS AND DISCUSSION

With the aim of checking the validity of our model, we have fitted three relaxation phenomena of a different nature: (i) magnetic (which is one of the most studied scenarios), taken from experiments with polycrystalline samples of magnetite (Fe₃O₄), (ii) dielectric (widely studied by Jonscher), with commercial samples of the polyacrylic acid Carbopol 907 (Ref. 16) of interest for pharmaceutical applications, and (iii) simulated data.

All the examples are first-order processes: The magnetic relaxation of Fe₃O₄ in the temperature window 250<T(K)<350 is governed by the diffusion of vacancies that can be described by Eq. (1) (which in fact is a diffusionlike equation). Our dielectric relaxation is an RC discharge, typically described by equations like Eq. (1). Finally, the equations that give rise to the simulated data fall also in the case of Eq. (1), as we will show later.

A. Magnetic relaxation

We measured the magnetic permeability, \(\mu_r\), of polycrystalline magnetite, Fe₃O₄, after a well-defined demagnetization of the sample (magnetic disaccommodation technique). Two processes are clearly distinguishable (Fig. 2, inset). The first one can be attributed to irreversible movements of the domain walls just after demagnetization processes, with topological discontinuities. The second can be attributed to reversible displacements after achieving the final topology. Both are well fitted with Eq. (11), with \(\gamma\) increasing with temperature in the range 0.2-1 and \(\gamma=5\), respectively. Arrhenius fits of \(\tau\) (Fig. 2) give similar activation energies (0.9 and 1.0 eV, respectively) that suggest that the damping of the movement of the walls in both processes must be produced by the same mechanism.

B. Dielectric relaxation

The model was checked with real data taken from the dielectric relaxation at 270 K of Carbopol 907, where \(\psi\) is the potential difference between faces after application of an electric current pulse. The sample was prepared from the raw material, supplied as powder. It was compacted to obtain disks with diameter 13 mm and thickness 1 mm. The faces were polished and painted with a conductive coat of graphite, in order to ensure for them constant potentials. In this way, we avoid additional relaxation processes due to the charge redistribution at the surfaces.

The final part of the curve (Fig. 3, inset) (stationary regime) is well fitted with Eq. (26). The best proof for the idoneity of the power law in this case is that, upon variation of the interval \((t_1,t_2)\), the parameters of the fit remain reasonably stable in a relatively significative time interval, with \(\gamma\approx4.6\), in contrast with the results from fits to a stretched exponential (Fig. 3).

C. Simulated data

We made simulations on simple models, in order to obtain the stationary regime in a reasonable time. The model consists of a lineal chain of \(N\) elements \(x_i\) that relax through nonlinear interaction with nearest neighbors. The elements \(x_0\) and \(x_{N-1}\) interact among them, therefore the system can be interpreted as a periodic chain of period \(N\) or a ring. In each iteration (time increase \(\Delta t\)), there are \(x_i\) increments in a given quantity.
FIG. 3. (Color online) Inset: Representation of the dielectric relaxation of polyacrylic acid according to our proposal. Note the good fit of the left part of the graph (corresponding to the longer times). Main frame: τ’s obtained after fittings to power-law and stretched exponential equations upon variation of the fitted time interval [(t1, t2); t2 = 1 s]. In the case of power-law fits, the obtained τ’s show a more constant trend, suggesting their validity.

\[ \Delta x_i = \Delta t[(x_{i-1} - x_i)(x_{i+1} - x_i)^{\lambda-1} + (x_{i-1} - x_i)(x_{i-2} - x_i)^{\lambda-1} - 1], \quad \lambda \gg 1 \]  

or

\[ \Delta x_i = \Delta t(x_{i-1} + x_{i+1} - 2x_i)(x_{i-1} + x_{i+1} - 2x_i)^{\lambda-1}, \quad \lambda \gg 1. \]  

These equations are the unidimensional and discrete version of the following diffusion like equations:

\[ \nabla \cdot (|\nabla x|^{\lambda-1} \nabla x) - \frac{\partial x}{\partial t} = 0 \]  

and

\[ |\nabla^2 x|^{\lambda-1} \nabla^2 x - \frac{\partial x}{\partial t} = 0 \]  

that fall within the cases described by Eq. (1).

In order to obtain a reasonable number of cases, the process starts with random \( x_i \) values with Gaussian distribution (an example is shown in Fig. 4). Besides this, we also proved “ordered” initializations including periodic sequences of periods \( N/2, N/3, \ldots \). Before starting a new process, the total average value is subtracted to each element (so that \( \langle x_i \rangle = 0 \)), in order to avoid premature rounding off effects in the procedure.

We choose as magnitude \( \psi \) the root-mean-square value of the \( x_i \),

\[ \psi = \sqrt{\frac{1}{N} \sum_{i=1}^{N} x_i^2}. \]  

Simulations were made for \( \lambda = 1.0, 1.2, 1.5, 1.8, 2.0, 2.5, 3.0, \) and 5.0, varying \( \Delta t \) and \( N \) (typically \( \Delta t = 0.05 \) and \( N = 64 \)). The higher \( \lambda \), the slower the process. With \( \lambda = 5 \), we had to increase \( \Delta t \) during the process, keeping \( \Delta \psi / \psi \) in reasonable values. Anyway, we checked that with smaller \( \lambda \), the result is the same as when keeping constant \( \Delta t \) during the process.

In all cases, the final regime is of the type described by Eq. (11). We verified this checking that the parameters of the fit to Eq. (26) do not change significantly upon changing the point intervals used. Given the random initial conditions, the amplitude \( \psi_0 \) and the time \( \tau \) needed to achieve the stationary regime are also random. Instead, \( \gamma \) depends only on \( \lambda \), and is coincident with the value given by Eq. (12) that corresponds to a simple relaxor following Eq. (9), with a deviation below 0.1% (with \( \lambda = 1 \) we obtain \( \gamma > 100 \)).

The case \( \lambda = 1 \) corresponds to a linear relaxation. For \( \lambda < 1 \) and long times \( \Delta t \to -2x_i \), and the process enters an oscillatory regime that cannot be regarded as of first-order, which led us to discard such cases.

\( \gamma \) is invariant under a change of the time origin, and therefore it could be given a physical meaning. In the simulations, \( \gamma_0 = 1/(\lambda - 1) \), corresponding to the stationary process, is characteristic of local interactions. The other (pseudostationary) processes, which depend on the time initialization, have smaller \( \gamma \)’s. This trend in \( \gamma \) has been observed in all the simulations, and it points to a link of \( \gamma \) with the complexity of the process (i.e., the smaller \( \gamma \), the more complex the process).

This interpretation is coherent with the results obtained in Fe$_3$O$_4$, where the irreversible relaxation after demagnetization is especially complicated, and involves slow diffusion processes in each new domain configuration together with magnetic interaction between domains. The velocity of the slow processes increases with temperature, enabling their coordination, and it leads to the increase of \( \gamma \), as expected. When the domain walls arrive at the final topology, the coordination is maximum, and the system goes to the stationary regime with the highest \( \gamma \).
We conclude then, on the basis of quite general conditions, that the relaxation process of first-order follows a power-law time decay on approaching the stationary limit, which is checked in real as well as in simulated data. We propose also a graphical representation that allows the view of the whole process in a finite window, independently of time.

APPENDIX

Fits

The fit to Eq. (11) in the general case with unknown $\psi_0$ and $\psi_\infty$ is done in two steps, first by calculating $\psi_0$, $\gamma$, and $\psi_\infty$ by means of

$$\frac{d\psi}{d \ln t} = -\gamma(\psi - \psi_\infty) \left[1 - \left(\frac{\psi - \psi_\infty}{\psi_0}\right)^{1/\gamma}\right],$$  \hspace{1cm} (A1)

and second by calculating $\tau$ with the following fit:

$$\frac{\psi'}{\psi_0} = -\frac{1}{\tau} \left(\psi - \psi_\infty\right)^{(\gamma+1)/\gamma}$$  \hspace{1cm} (A2)

keeping $\psi_0$, $\gamma$, and $\psi_\infty$ constant.

Analogously, the fit to Eq. (17) is done calculating $\psi_0$, $\beta$, and $\psi_\infty$ by means of

$$\frac{d\psi}{d \ln t} = \beta(\psi - \psi_\infty) \frac{2}{\ln 2} \ln \left(\frac{\psi - \psi_\infty}{\psi_0}\right)$$  \hspace{1cm} (A3)

and then calculating $\tau$ with the usual fit, with fixed $\psi_0$, $\beta$, and $\psi_\infty$.

Calculation of the derivatives

For the fit indicated by Eq. (A1), two procedures were followed.

(a) Least square fit: we took an interval of $n$ data consecutive in time $t$, and they were fitted to a polynomial of grade $K$,

$$P(t) = \sum_{k=0}^{K} a_k (t - \langle t \rangle)^k,$$  \hspace{1cm} (A4)

where $\langle t \rangle$ is the mean value of $t$ in such an interval. The fit is weighed, using as the weight function $\rho$ the square of Hanning’s window. From the coefficients of the fit,

$$\psi(\langle t \rangle) = a_0,$$

$$\psi'(\langle t \rangle) = a_1,$$

$$\frac{d\psi}{d \ln \rho} (\langle t \rangle) = \langle t \rangle a_1.$$  \hspace{1cm} (A5)

With simulated data, without noise, the best results are attained with $K \gg n \gg K+1$. This procedure works well, even with data unequally spaced in time, and it filters noise, as the results are, in a certain sense, the average of the $n$ points.

(b) Convolution: The same data interval is convoluted with a function $\eta$, in order to obtain $\langle t \rangle$ and $\langle \psi \rangle$, and with another $\eta'$ to obtain $\langle \psi' \rangle$. $\eta$ and $\eta'$ are obtained from $\rho$ and $\rho'$ by an orthogonalization procedure with respect to the values of $t$ in the points of the interval (that may not be uniformly spaced). It could be said that the procedure is a discretization of the averages,

$$\langle \psi \rangle = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} \rho \psi \, dt,$$

$$\langle \psi' \rangle = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} \rho \psi' \, dt = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} \rho' \psi \, dt.$$  \hspace{1cm} (A6)

with $\rho(t_1) = \rho(t_2) = 0$.

With exact data, the precision of this procedure was somewhat worse than the previous one, but its sensitivity to noise is lower instead, which makes it useful for the processing of experimental data.
